(Received 1 March 2020; revised 19 July 2020; accepted 16 August 2020; published 31 August 2020)

We investigate the Landau-Zener-Stückelberg-Majorana interferometry of a superconducting qubit in a semi-infinite transmission line terminated by a mirror. The transmon-type qubit is at the node of the resonant electromagnetic (EM) field, “hiding” from the EM field. We modulate the resonant frequency of the qubit by applying a sinusoidal flux pump. We perform spectroscopy by measuring the reflection coefficient of a weak probe in the system. Remarkable interference patterns emerge in the spectrum, which can be interpreted as multiphoton resonances in the dressed qubit. Our calculations agree well with the experiments.

DOI: 10.1103/PhysRevB.102.075448

I. INTRODUCTION

In recent years, superconducting artificial atoms [1] coupled to an open transmission-line waveguide have been a fast growing field, called waveguide quantum electrodynamic (w-QED), which provides a unique platform to investigate atom-light interactions. The uniqueness of w-QED, as compared to conventional cavity QED, is that atoms are coupled to continuum modes of the electromagnetic (EM) field in the waveguide. Exciting problems in w-QED include resonance fluorescence of an artificial atom [2], photon-mediated interactions between distant artificial atoms [3], an atom in front of a mirror [4], time dynamics in atom-like mirrors [5], photon routing [6], generation of nonclassical microwaves [7], the cross-Kerr effect [8], amplification without population inversion [9], the collective Lamb shift between two distant artificial atoms [10], ultrastrong coupling [11], quantum riffling [12], probabilistic motional averaging [13], and the dynamical Casimir effect [14–17].

When a two-level system is driven back and forth around its resonance frequency, it will produce Landau-Zener-Stückelberg-Majorana (LZSM) interference. LZSM interferometry [18–20] has been studied in atomic systems [21], quantum dots [22,23], charge and spin qubits [24,25], and a superconducting qubit in a cavity [26–29], among other areas. However, the effect of LZSM has not been explored with a single artificial atom in front of a mirror, where the artificial atom is coupled to a continuum of modes of the EM field in the transmission-line waveguide, and the atom interferes with its mirror image, as in Refs. [4,30].

LZSM interferometry is important for both system description and control [31,32]. However, for this to be realized, one needs to have the avoided energy-level crossing in the spectrum as a function of a controlling parameter. One example of systems without this are transmon-type superconducting qubits, where the energy levels are almost independent of the gate voltage. The way to fix this was studied in Ref. [33], which studied the qubit by chirping the microwave frequency, which results in dressed states with avoided-level crossing. In this work, we study a transmon qubit driven by two fields (see also Ref. [34]). One of these dresses the qubit and creates the spectrum with the avoided-level crossing, while the other one makes the system periodically pass around the avoided-level point. This allows us to study LZSM interferometry in a qubit placed in front of a mirror. We could refer to our system as “mirror, mirror”, because the qubit acts as another mirror.

II. SUPERCONDUCTING QUBIT IN FRONT OF A MIRROR

In this work, we investigate the LZSM interferometry of a superconducting qubit in a semi-infinite transmission line, at a distance terminated by a mirror. In particular, the qubit is located at the node of the resonant EM field, where it is hiding from the EM field. We then modulate the resonant frequency of the qubit by applying a sinusoidal wave through an on-chip flux pump. In addition, the qubit is also coupled to the microwave probe signal applied to the transmission line. We then perform the spectroscopy of the system by applying a...
FIG. 1. The experimental setup and device. (a) A conceptual sketch of the device showing the electromagnetic mode (red curve) in the transmission line. The qubit is located at the node of the resonant mode of the EM field, hiding from the EM field. The qubit is subjected to a sinusoidal drive along the transmission line with frequency $\omega_p$ and a flux pump $\omega_{\text{pump}}$. (b) A photo of the device. The qubit (shown in the zoom-in on the left; the two long bright parts form the qubit capacitance, and the gap in the middle between them is bridged by two Josephson junctions forming a SQUID loop) is placed $L \approx 33$ mm from another qubit, which sits at the end of the transmission line (i.e., at the mirror). Note that the qubit at the end of the transmission line is not in use in this work because it is far detuned. The characteristic impedance of the transmission line is $Z_0 \approx 50 \Omega$. By tuning the qubit transition frequency $\omega_{10}$, we tune the qubit to the node of the EM field. (c) A sketch of the setup for the experiment. The qubit frequency $\omega_{10}$ can be tuned by a global magnetic field from a superconducting coil controlled by a dc voltage $V$. For measurements, a coherent signal at frequency $\omega_p$ is generated by a vector network analyzer (VNA) at room temperature and fed through attenuators (red squares) to the sample, which sits in a cryostat cooled at 20 mK to avoid thermal fluctuations affecting the experiment. The reflected signal passes a bandpass filter (BPF) and amplifiers and is then measured with the VNA. Here $\omega_{\text{pump}}$ relates to the flux pump to modulate the transition frequency of the qubit.

The qubit is embedded in a semi-1D transmission line with characteristic impedance $Z_0 \approx 50 \Omega$, with the ground state $|0\rangle$ and the excited state $|1\rangle$. The $|0\rangle \leftrightarrow |1\rangle$ transition energy is

$$\hbar \omega_{10}(\Phi) \approx \sqrt{8E_J(\Phi)E_C - E_C},$$

which is determined by the single-electron charging energy $E_C = e^2/2C_\Sigma$, where $C_\Sigma$ is the total capacitance of the qubit, and the flux-dependent Josephson energy $E_J(\Phi) = E_{J,\text{max}} \cos(\pi \Phi/\Phi_0)$; $\Phi_0 = h/2e$ is the magnetic flux quantum. The ratio $E_C/E_J$ determines the anharmonicity of the qubit.

In Fig. 1(c) a probe field of frequency $\omega_p$ is fed into the transmission line. The pump field of frequency $\omega_{\text{pump}}$ is applied to the on-chip flux line, sinusoidally modulating the transition frequency of the qubit. The key parameters are summarized in Table I.

III. THEORETICAL DESCRIPTION

Let us now consider the qubit Hamiltonian, with details presented in Appendix A. Due to the mirror, the transmission-line voltage at the point of coupling the qubit, $x = L$, is proportional to $\cos(\omega_{\text{node}}L/v)$. When this factor is zero, this gives the node frequency $\omega_{\text{node}}$, with $\cos(\omega_{\text{node}}L/v) = 0$. For small frequency offset,

$$\Delta \omega = \omega_p - \omega_{\text{node}} \ll \omega_p,$$

which is determined by the single-electron charging energy $E_C = e^2/2C_\Sigma$, where $C_\Sigma$ is the total capacitance of the qubit, and the flux-dependent Josephson energy $E_J(\Phi) = E_{J,\text{max}} \cos(\pi \Phi/\Phi_0)$; $\Phi_0 = h/2e$ is the magnetic flux quantum. The ratio $E_C/E_J$ determines the anharmonicity of the qubit.

In Fig. 1(c) a probe field of frequency $\omega_p$ is fed into the transmission line. The pump field of frequency $\omega_{\text{pump}}$ is applied to the on-chip flux line, sinusoidally modulating the transition frequency of the qubit. The key parameters are summarized in Table I.

we can expand the cosine into series; then instead of \( \cos(\omega_p t/\nu) \), we have \( \Delta \omega/\omega_{\text{node}} \). This means that at \( \Delta \omega = 0 \) the qubit is “hidden” or “decoupled” from the transmission line. So we have the Hamiltonian

\[
H = -\frac{B_z}{2} \sigma_z - \frac{B_x}{2} \sigma_x, \tag{3}
\]

of which the diagonal part is the energy-level modulation

\[
B_z/\hbar = \omega_{10} + \delta \sin \omega_{\text{pump}} t, \tag{4}
\]

and the off-diagonal part describes the coupling to the probe signal

\[
B_x/\hbar = G \sin \omega_{\text{pump}} t. \tag{5}
\]

Importantly, here the coupling constant \( G \) is proportional to the frequency offset \( \Delta \omega \),

\[
G = G_0 \frac{\Delta \omega}{\omega_{\text{node}}}, \tag{6}
\]

and \( G_0 \) is proportional to the probe signal amplitude.

The observable value is the reflection coefficient \( r \), namely, its deviation from 1. The impact of the qubit is in suppressing \( \sim \omega_{\text{node}} \). Sinusoidal driving \( f(t) \), shown at the bottom, makes the system evolve periodically between \( \Delta \omega - \delta \) and \( \Delta \omega + \delta \). For small energy-level splitting \( G \) and strong driving (with large amplitude \( \delta \)), the resonant excitation of the system can equivalently be described either in terms of sequential LZSM transitions or in terms of multiphoton excitations, at \( \Delta \omega = k\omega_{\text{pump}} \).

This is described by the phase, accumulated by the vector-state during one period,

\[
\zeta = \int_0^{2\pi/\omega_{\text{pump}}} dt \Delta \tilde{E}/\hbar \approx \frac{\Delta \omega}{\omega_{\text{pump}}} \frac{2\pi}{\omega_{\text{pump}}}. \tag{12}
\]

Here the approximation means the assumption of small splitting and strong driving: \( G \ll \delta \). When the phase \( \zeta \) equals to \( 2\pi k \), with an integer \( k \), the system is resonantly excited. Then from \( \zeta = 2\pi k \) the resonance condition becomes

\[
\Delta \omega = k\omega_{\text{pump}}. \tag{13}
\]

This can be interpreted as a multiphoton excitation, meaning that the system is resonantly excited when the dressed energy gap \( \hbar \Delta \omega \) equals the energy of \( k \) photons, \( k\hbar \omega_{\text{pump}} \).

Quantitatively, from the stationary solution of the Bloch equations with the Hamiltonian \( H_1 \), in the rotating-wave approximation, for the upper-level occupation probability we have (see, e.g., Refs. [40,41]):

\[
P_1 = \frac{1}{2} \sum_{k=\infty}^{\infty} \frac{G^2_k}{G^2_k + \Gamma_1 \Gamma_2 \hbar \omega_{\text{pump}}} + \Gamma_1 \Gamma_2, \tag{14}
\]

where the renormalized driving amplitude

\[
G_k = G J_k(\delta/\omega_{\text{pump}}). \tag{15}
\]

follows the oscillating Bessel function \( J_k \) of the first kind; \( \Gamma_1 \) and \( \Gamma_2 = \Gamma_1/2 + \Gamma_0 \) are the relaxation and decoherence rates,
We first perform single-tone spectroscopy of the qubit-mirror system. In Fig. 3 the resonant frequency of the qubit is tuned by voltage. As the voltage increases, the linewidth of the qubit decreases from a finite linewidth to zero, and then increases back to a finite linewidth. At the frequency where the linewidth vanishes, around $\omega_{10} = \omega_{\text{node}} \simeq 4.75$ GHz, the qubit is located at the node of the EM field, as indicated by the vertical dashed line, where it is hiding from the EM field.

By using two-tone spectroscopy [10], we know that $E_C/h \simeq 324$ MHz. For $\omega_{10}/2\pi = 4.75$ GHz, the corresponding Josephson energy is $E_J/h \approx 9.9$ GHz.

After the basic characterization of the system, we want to study the spectrum as a function of the following parameters: qubit frequency $\omega_{10}$, pump amplitude $\delta$, pump frequency $\omega_{\text{pump}}$, and probe frequency $\omega_p$. For spectroscopy, we always use the probe power of $-130$ dBm in experiments.

To start, we set the qubit frequency corresponding to the node as a working point, where $\omega_{10} = \omega_{\text{node}}$. We then apply a sinusoidal flux pump at a fixed power to the qubit and sweep the pump frequency from 1 MHz to 100 MHz. At the same time, we perform the spectroscopy of the system using a weak field, with the frequency $\omega_p$ near the qubit frequency.

We show the amplitude reflection coefficient $|r|$ in Figs. 4(a) and 4(b) as a function of $\omega_p$ and $\omega_{\text{pump}}$ in Fig. 4(a) for $P_{\text{pump}} = -45$ dBm and in Fig. 4(b) for $P_{\text{pump}} = -38$ dBm. We observed LZSM interference fringes. These interference fringes can be interpreted as multiphoton resonances in the dressed qubit. Multiphoton resonances appear at $\omega_p = \omega_{10} \pm k \omega_{\text{pump}}$, where $k$ is the order, as indicated in the figures. The zero order, where $k = 0$, is missing, which is a key feature here, different from conventional LZSM interference fringes. In Fig. 4(b) we can clearly see the order $k$ up to $\pm 4$. We increase the pump power in Fig. 4 from $-45$ dBm in Fig. 4(a) to $-38$ dBm in Fig. 4(b), and the gap between negative $k$ and positive $k$ fringes becomes wider. Indeed, the stronger the pump power, the wider they separate (data not shown). The power in Figs. 4(a) and 4(b) differs by 7 dB, meaning that their pump amplitude $\delta$ differs by a factor of 2.2. This is also what happens in the theory calculation plots. In this sense, this separation can be used to calibrate the pump power.

In Fig. 4(c) we bias the qubit at around 4.58 GHz, red-detuned from the node, and we then see asymmetric interference fringes. At this bias point, when the qubit is pumped in the negative part of the sinusoidal, the qubit is pumped toward the larger linewidth regime; see Fig. 3. However, when the qubit is pumped in the positive part of the sinusoidal, the qubit is pumped toward the zero-linewidth regime; therefore, we can see that the interference fringes vanish near $\omega_{\text{node}}$. In addition, in contrast to Fig. 4(a) and 4(b), the $k = 0$ zero Rabi sideband appears in Fig. 4(c) because there the qubit is biased away from the node.

Next, we keep the pump frequency $\omega_{\text{pump}}$ constant. We change the power of the pump $P_{\text{pump}}$ from $-70$ dBm to $-30$ dBm and probe the system with a weak field near the resonance frequency of the qubit. In Fig. 5 we show in Fig. 5(a) and Fig. 5(b) $\omega_{\text{pump}}/2\pi = 10$ MHz and 100 MHz for the qubit frequency at the node $\omega_{\text{node}}$, and $\omega_{\text{pump}}/2\pi = 10$ MHz for

\[ 1.5\]

\[ 2.5\]

\[ 3.5\]

\[ 4.5\]

FIG. 3. Spectroscopy of the system. (a) Amplitude of the reflection coefficient $|r|$ at a coherent probe power of $-130$ dBm as a function of probe frequency $\omega_p$ and qubit frequency $\omega_{10}$ (controlled by the voltage $V$). The spectroscopy shows how the response disappears when the qubit ends up at a node for the EM field around $\omega_p = \omega_{\text{node}} \simeq 4.75$ GHz, denoted by the dashed line marker. The red dot indicates the qubit bias point in Figs. 4(a) and 4(b) and Figs. 5(a) and 5(b). The blue dots correspond to the qubit bias point in Fig. 4(c) and Fig. 5(c), respectively. The inset shows the calculated qubit upper-level occupation probability $P_1$ as a function of the probe frequency $\omega_p$ and the qubit frequency $\omega_{10}$ (both in GHz$2\pi$). (b) For a given bias voltage in (a), it is a Lorentzian dip (data not shown) indicating that the qubit reflects the resonant probe field. The qubit acts as a mirror, reflect the resonant field. We extract the resonant frequency $\omega_{10}$, relaxation rate $\Gamma_1$, and pure dephasing rate $\Gamma_0$ following Ref. [42], taking into account the effect of the Rabi frequency. In particular, we convert the probe power to Rabi frequency at a resonant frequency of 5.05 GHz using calibration data in Ref. [10] (same sample, but in a different cool down). Moreover, the Rabi frequency at each resonant frequency is given by Eq. (4).

Finally, we see $\omega_{10} \propto V$; however, in general, for the wide range of voltage bias, this is not the case; see details of the flux dependence in Ref. [10].

with the pure dephasing rate $\Gamma_0$ being much smaller than $\Gamma_1$. One can see that the maximum of $P_1$ is indeed defined by the condition (13). With this formula, Eq. (14), we plot theoretical graphs in Figs. 3, 4, and 5. For details see Appendix B.

V. MEASUREMENTS
FIG. 4. Sinusoidal modulation of the qubit by flux pumping, with the resonance frequency at a fixed pump power $P_{\text{pump}}$. Amplitude reflection coefficient $|r|$ for a weak coherent probe as a function of the probe frequency $\omega_{\text{p}}$ and pump frequency $\omega_{\text{pump}}$; panels (a)–(c) are experimental data, and (d)–(f) are our theoretical calculations. (a) Qubit biased at $\omega_{\text{node}} = 4.75 \text{ GHz}$; the flux pump power is fixed at $P_{\text{pump}} = -45 \text{ dBm}$. (b) Qubit biased at the node around 4.75 GHz with $P_{\text{pump}} = -38 \text{ dBm}$. (c) Qubit biased at 4.58 GHz, red detuned from the node, and $P_{\text{pump}} = -38 \text{ dBm}$. Note that the $k$-dependent multiphoton resonances emerge: $\Delta \omega = k \omega_{\text{pump}}$, which are shown by the inclined red dashed lines. In panel (b) we can see Rabi sidebands for $k$ from $-4$ to $4$. In panels (a) and (b), the $k = 0$ Rabi sideband disappears, whereas in panel (c) the $k = 0$ Rabi sideband appears. For panels (a) and (b), the positive $k$ and negative $k$ fringes are symmetric, whereas in panel (c) the interference fringes are not symmetric along $k = 0$. As the fringes approach the node regime, near 4.75 GHz, they become weaker. In panels (d)–(f) we show the respective calculated qubit upper-level occupation probabilities $P_1$. Experimentally, the pump power reached at the sample is slightly frequency dependent. The low-frequency flux pumping drive (say, 1 MHz) has about 1 dB higher power than the high-frequency flux pumping drive (say, 20 MHz). Therefore, we see that the $\omega_{\text{pump}}$ at low frequency has more shift $\delta$ in the data.

the qubit frequency red detuned from $\omega_{\text{node}}$ in Fig. 5(c). These plots show the amplitude reflection coefficient $|r|$ as a function of the probe frequency $\omega_{\text{p}}$ and the pump power $P_{\text{pump}}$. In Figs. 5(a) and 5(b), when the flux pump is weak (this corresponds to a small change of the qubit resonance frequency) there are no interference fringes in the interference pattern. This can be explained using Fig. 3, where the “node regime” corresponds from 4.7 GHz to 4.8 GHz, and there is no response for a weak flux pump. When the pump power increases, this corresponds to larger changes of the resonance frequency, and we see the Rabi-splitting-like behavior in Fig. 5(a). In Fig. 5(b) Rabi sidebands at $k = -2, -1, +1, +2$ appear. These match the condition $\Delta \omega = k \omega_{\text{pump}}$. The higher the pump power, the more resolved the sideband $k$ becomes. In Fig. 5(c), when we bias the qubit frequency away from $\omega_{\text{node}}$, the interference fringes become weaker as the probe frequency approaches the node frequency at 4.75 GHz.

VI. CONCLUSIONS

In conclusion, we investigate the LZSM interferometry of a superconducting qubit in a semi-infinite transmission line terminated by a mirror. When the qubit frequency is set to the node of the EM field, after flux pumping the qubit frequency, remarkable interference patterns emerge, which can be interpreted as multiphoton resonances in the dressed
FIG. 5. Sinusoidal modulation of the qubit by flux pumping at the resonance frequency at a fixed pump frequency $\omega_{\text{pump}}$. The plots show the amplitude of the reflection coefficient $|r|$ for a weak coherent probe versus the probe frequency $\omega_p$ and pump power $P_{\text{pump}}$. Panels (a)–(c) correspond to experiments and (d)–(f) to theory. Panels (a) and (b) are at the node around 4.75 GHz with $\omega_{\text{pump}}/2\pi = 10$ MHz and 100 MHz, respectively. Note the Rabi sidebands at $\Delta \omega = k\omega_{\text{pump}}$, with $k = -2, -1, 1, +2$. The higher the pump power, the more resolved sidebands are visible. Note the onset of the Rabi sidebands for $k = \pm 1$ and $k = \pm 2$, for $-45$ dBm and $-35$ dBm, respectively. (c) Red detuned from the node at 4.56 GHz. In panels (a) and (c), we observe Rabi-like splittings as the pump power increases. In panel (a) we see a symmetric splitting, whereas in panel (c) there are several asymmetric splittings. In panel (c), as the fringes approach $\omega_{\text{node}}$, they become weaker. In panels (d)–(f) we show the respective calculated qubit upper-level occupation probabilities $P_1$. We see multiphoton resonances up to the fourth order. Since the qubit interferes with its mirror image, the zero-order photon resonance disappears. Such an effect would not appear in the case of an infinite transmission line. One of the advantages of this atom-mirror arrangement is that we can effectively manipulate the absorption properties of the two-level atom, providing a novel way to manipulate the quantum states.

APPENDIX A: HAMILTONIAN

In this Appendix we describe how we obtain the Hamiltonian (3) for a qubit in front of a mirror, schematically shown in Fig. 6; see also Ref. [43].

The transmission line is described by the voltage \( V(x,t) \) and current \( I(x,t) \):

\[
V(x,t) = V(x)e^{i\epsilon t}, \quad I(x,t) = I(x)e^{i\omega t}, \quad (A1)
\]

with

\[
V(x) = V_+ e^{ikx} + V_- e^{-ikx},
\]

\[
I(x) = -\frac{V_+}{Z_0} e^{ikx} + \frac{V_-}{Z_0} e^{-ikx}, \quad (A3)
\]

where \( k = \omega_p/v \). Due to the mirror at \( x = 0 \), we have \( I(0) = 0 \), \( V_- = V_+ \), and \( V(x) = 2V_+ \cos(kx) \) for \( x \in (0,L) \).

The transmon is described by the number operator \( n \) of Cooper pairs on it, with the number operator \( n \) given by the Pauli matrix [44]

\[
n = n = \left( \frac{E_1}{32E_C} \right)^{1/4} \sigma_x. \quad (A4)
\]

If we take here \( \hbar \omega_{10} \approx \sqrt{8E_CE_1} \), we have

\[
n = \sqrt{\frac{\hbar \omega_{10}}{E_C}} \sigma_x. \quad (A5)
\]

Then, writing the charges of the respective capacitor plates, we obtain the island voltage [45]

\[
V_1 = \frac{2e}{C_\Sigma} n - \frac{C_c}{C_\Sigma} V(L,t), \quad (A6)
\]

which can be rewritten (omitting c-numbers) as follows:

\[
H_c = \frac{1}{2}C_c[V(L,t) - V_1^2] \rightarrow C_c[V(L,t)V_1]
\]

\[
\rightarrow eV_+ \frac{C_c}{C_\Sigma} \sqrt{\frac{\hbar \omega_{10}}{E_C}} \cos \left( \frac{\omega_p}{v} L \right) \sin(\omega_p t) \sigma_x. \quad (A7)
\]

For a small frequency offset, \( \Delta \omega = \omega_p - \omega_{\text{node}} \ll \omega_p \), we have

\[
\cos \left( \frac{\omega_p}{v} L \right) \approx \frac{\pi}{2} \Delta \omega, \quad (A8)
\]

with \( \cos(\omega_{\text{node}} L/v) = 0 \). Then the Hamiltonian (A7) describes the off-diagonal part of the transmon Hamiltonian (3) with

\[
G = G_0 \frac{\Delta \omega}{\omega_{\text{node}}},
\]

\[
G_0(V_+) = \frac{\pi}{\hbar} \frac{C_c}{C_\Sigma} \sqrt{\frac{\hbar \omega_{10}}{E_C}} V_+, \quad (A9)
\]

This is written in the main text as Eq. (5).

Consider next the diagonal part of the transmon Hamiltonian given by the energy-level splitting in Eq. (1).

The flux contains the dc and ac components, \( \Phi = \Phi_{dc} + \Phi_{ac} \sin(\omega_{\text{pump}} t) \). Assuming the latter being a small value, we obtain

\[
\hbar \omega_{10} = \hbar \omega_{10}(\Phi_{dc}) + \hbar \delta(\Phi_{ac}) \sin(\omega_{\text{pump}} t), \quad (A10)
\]

where \( \delta(\Phi_{ac}) \propto \Phi_{ac} \) is the driving amplitude. This is written in the main text as Eq. (4).

APPENDIX B: DETAILS OF THE CALCULATIONS AND THE ROLE OF NONLINEARITY

For obtaining theoretical graphs (Figs. 3, 4, and 5), we solve Eq. (14) in each point of the 2D plots. The amplitude \( \delta \) was derived from the lowest pump frequency \( \omega_{\text{pump}} \), where the first resonance lines vanish, as shown with the yellow double arrow in Fig. 7(a). We choose this because in the experiment, the sidebands become shifted at low \( \omega_{\text{pump}} \). We assume that the shift is due to the nonlinearity and take this into account as \( \delta = \delta(\omega_{\text{pump}}) \) below.

The relaxation rate \( \Gamma_1 \) and the dephasing rate \( \Gamma_\phi \) are estimated from the experimental data in Fig. 3(b). We find \( \Gamma_2 \) from the expression \( \Gamma_2 = \Gamma_1/2 + \Gamma_\phi \). The parameter \( G_0 \) is the fitting parameter, and we take this equal to 0.1 GHz \( h \).

In Fig. 7 we show details of how we calculate the interferograms and compare with the experiments. Figure 7(b) is the same as Fig. 4(f), in Fig. 7(c) we take into account the nonlinearity, and in Figs. 7(c)–7(e) we can see a good agreement between the location and relative depth of the resonances in the experiment (denoted as Expt) and theory (denoted as Thry) for the high \( \omega_{\text{pump}} \) frequency, but in the area with low \( \omega_{\text{pump}} \) we can see increasing the space between the sidebands.

In the theory, the location of the sidebands with \( \omega_{\text{pump}} = 0 \) is defined by the amplitude \( \delta \), and these are located at \( \omega_{10} \pm \delta \). From this difference we suggested that in the area of low pump frequency, \( \omega_{\text{pump}} \rightarrow 0 \), the amplitude \( \delta \) is increased. We take such nonlinearity into account and use this dependence...
FIG. 7. (a) Reflection coefficient as a function of the probe frequency $\omega_p$ and the pump frequency $\omega_{pump}$, as in Fig. 4(c). (b) Upper-level occupation probability $P_1$, calculated for the same parameters as Fig. 4(f). (c) Similar interferogram with taking into account the phenomenological nonlinearity, Eq. (B1). (d)–(f) The cross sections taken at different values of the pump frequency, $\omega_{pump}/2\pi = 60, 30, 20$ MHz, respectively. Panels (d) and (e) demonstrate agreement of the theoretical calculations (red and green curves) with the experimental data from (a) (black curves) for high-pump frequency, while (f) demonstrates the deviation of the theory with constant $\delta$ (blue curve) from the experiment. The modified theory, with nonlinear $\delta'(\omega_{pump})$, the brown curve, is in much better agreement.

for obtaining a better agreement between the theory and the experiments in the low pumping frequency regime. For this, instead of constant $\delta$, we empirically consider

$$\delta'(\omega_{pump}) = \delta + (1 - \omega_{pump}/G_0)^8 \delta.$$  \hspace{1cm} (B1)

Then the obtained interferogram [Fig. 7(c)] is in agreement with the experimental Fig. 7(a). This agreement can also be seen in Fig. 7(f), where the brown curve is for the modified theory (denoted as Thry mod).

APPENDIX C: MICROWAVE SIMULATION OF END CAPACITOR USING HIGH-FREQUENCY STRUCTURE SIMULATOR

We use the 3D electromagnetic simulation software “High-Frequency Structure Simulator” to simulate the end capacitance in the transmission line and the phase shift caused by it. The value of the capacitance (mirror) is about 1.3 fF [see Fig. 8(b)], and the phase shift caused by the mirror is less than $0.3^\circ$; see Fig. 8(c). As expected, the phase shift is very close to the phase shift produced by an ideal mirror, which is zero.
FIG. 8. Simulation using High-Frequency Structure Simulator. (a) Electric field distribution of a transmission line with an end capacitor, acting as a mirror. (b) The capacitance calculated from the simulated input impedance $Z$, where $Z = 1/(\omega C)$. (c) Phase response of the simulated reflection coefficient caused by the end capacitor.
